# Graph-based automatic program separation

#### Shen Liu

(Version 1.5, last modified 08/07/2016)

#### **Abstract**

Type conversion between C and protocol buffer is an important issue in our project. When the separation is done and the RPC tool begins working, we must automatically restore all the arguments for each RPC function in the receiver process, which means the function parameter types need to be transmitted between two processes fully and exactly. Unfortunately, the type system that protocol buffer supports is quite weak. To make our project automatically run in the end, we have to design a type conversion protocol to let protocol buffer automatically convert some advanced C types(e.g. pointer) into protocol buffer types.

# 1 Background

We use gRPC, which is fully based on google protocol buffer, to deal with RPC issues in our project. In gRPC, a C type must be packed to protocol buffer "message" type in a .proto file(IDL file) for further transmission. For example, if you have a C function int foo(int x) which needs to be called remotely, then in your .proto file, the argument type int can be packed in protocol buffer as follows:

message M{ int64 x=1; or int32 x=1

```
}
```

Next, protocol buffer will automatically generate a group of read/write APIs for each message. Here is an API for x's value assignment:

```
void set_x (::google::protobuf::int32 value);
and an API for getting the value of x:
   inline ::google::protobuf::int32 M::x() const {
    return x_;
}
```

Here is a more complex C-protobuf type conversion sample:

Our project can automatically finish this conversion for all scalar types and simple composite types as "Circle". However, when parameter types become more and more complex, especially for those structures with multilevel pointers, generating a correct .proto file automatically as before will be a real challenge. To achieve this goal, a possible way is designing a type-conversion protocol to make our project work more intelligently. Simply speaking, for any C type input, first we use such a protocol to convert it into an integer array(encoding), and then construct the "message" type in .proto. On the receiver side, we do array parsing to restore the original C types(decoding) instead of parsing the complex .proto file.

# 2 Type system and encoding/decoding rules

In this draft we only use a small subset of C type system to show how the encoding/decoding idea works. Here is how our toy type system looks like:

Any pair of form (type, value) based on this type system will be encoded as an array of bytes(bytes[] lst), and the first byte(see table 1) in this array denotes what type this array corresponds to.

lst[0]	type
0	int
1	pointer
2	struct $\{t_1; t_2;; t_n\}$
3	tname S

Table 1: type mapping rules

As we can see from Table 1, any encoding/decoding operation related to type tname S requires knowing the associative type struct{...} of tname S. In our framework, we use a name-type mapping table(e.g. table 2) to map each name string which represents a struct to its corresponding struct type.

name	struct
S1	struct {int;int;}
S2	struct {int;int*;}
S3	struct {int;int*; S1*;}
•••	•••

Table 2: A name-type mapping table example

Besides, in each round for encoding, we also use an auxiliary table called pointer table to record each pointer value that ever appeared. By doing this we can identify some complex function arguments(e.g. circular

## linked list).

Once we have such auxiliary tables, we can easily construct the encoding/decoding rules for our type system as follows:

Basic value conversion functions:

```
intToBytes(int): convert an integer to a byte string.
```

symbolToBytes(S): convert a symbol S to a byte string.

ptrToBytes(int): convert a pointer address(int) to a byte string.

bytesToInt(bytes[]): convert a byte string to an
 integer.

bytesToSymbol(bytes[]): convert a byte string to a symbol.

bytesToPtr(bytes[]) convert a byte string to a hexadecimal integer.

dereference(int): return the value that a pointer points to.

getTypeFromTable(S): look up S in the mapping table
 and return its
 associative type.

```
| tname S
            => 3::symbolToBytes(S)::encode(
               getTypeFromTable(S),v)
  end.
Definition decode bytes[] lst =
  match 1st [0] with
    0 \Rightarrow ((int, bytesToInt(lst[1...4])), lst+5)
    | 1 \Rightarrow let ((t1, dereference(v)), l1) = decode (lst)
       +5) in ((t1*, v), l1)
            //v = bytesToPtr(lst[1...4])
    | 2 \Rightarrow let n = bytesToInt(lst[1]) in
            let ((t1,v1),11) = decode (1st+5) in
         let ((t2,v2),l2) = decode l1 in
           let ((tn,vn),ln) = decode l_{n-1} in
           \{(t1,v1);(t2,v2);...;(tn,vn)\}, ln\}
    | 3 \Rightarrow \text{let } S = \text{bytesToSymbol}(1\text{st}[5...5 + \text{length}(S)])
        -1) in
                                   /*length(S) =
                                      bytesToInt(lst
                                      [1...4])*/
           decode(lst+offset) /* offset = 1+4+length(S
              ) */
  end
  Now consider a circular linked list example:
      typedef struct Node{
       int val;
       Node* next;
      } Node_t;
     Node_t *head = (Node_t*) malloc(size of (Node_t));
          //head: 0x0004
```

```
Node_t *tail = (Node_t*) malloc(size of (Node_t));
          //tail: 0x0008
      head \rightarrow val = 10;
      head->next = tail;
      tail \rightarrow val = 20;
      tail -> next = head; // circular linked list
  Assume that we want to send this circular linked list from sender to
receiver, then the encode/decode process is as follow:
encode (Node_t *head, 0x0004)
= 1::ptrToBytes(0x0004)
   :: encode(Node_t, dereference(0x0004))
   /* dereference(0x0004) = \{10,0x0008\} */
   (pointer table: \{0 \times 0004\})
= 1::ptrToBytes(0x0004)
   ::3::symbolToBytes(Node_t)
       :: encode (getTypeFromTable (Node_t), {10,0x0008})
   (pointer table: \{0 \times 0004\})
= 1:: ptrToBytes(0x0004)
   ::3::symbolToBytes(Node_t)
   ::encode(struct Node{int, struct Node*},{10,0x0008}
      })
   (pointer table: \{0 \times 0004\})
= 1::ptrToBytes(0x0004)
   ::3::symbolToBytes(Node_t)
       ::2::intToBytes(2) /*two fields*/
          :: encode (int ,10)
          :: encode(Node_t*, 0x0008)
```

```
(pointer table: \{0 \times 0004\})
= 1::ptrToBytes(0x0004)
   ::3::symbolToBytes(Node_t)
       ::2::intToBytes(2) /*two fields*/
          ::0::intToBytes (10)
          ::1::ptrToBytes(0x0008)
             ::3::symbolToBytes(Node_t)
                 :: encode (getTypeFromTable (Node_t),
                    dereference(0x0008)
   (pointer table: \{0 \times 0004, 0 \times 0008\})
= 1::ptrToBytes(0x0004)
   ::3::symbolToBytes(Node_t)
       ::2::intToBytes(2) /*two fields*/
          ::0:: intToBytes (10)
          ::1::ptrToBytes(0x0008)
             ::3::symbolToBytes(Node_t)
                 ::encode(struct Node{int, struct Node
                    *}, {20,0x0004})
   (pointer table: \{0 \times 0004, 0 \times 0008\})
= 1::ptrToBytes(0x0004)
   ::3::symbolToBytes(Node_t)
       ::2::intToBytes(2) /*two fields*/
          ::0:: intToBytes (10)
          ::1::ptrToBytes(0x0008)
             ::3::symbolToBytes(Node_t)
                 ::2::intToBytes(2) /*two fields*/
                    ::0::intToBytes (20)
                    :: 1:: ptrToBytes (0x0004)
```

```
(0x0004 is in pointer table already, stop here)

(pointer table: {0x0004, 0x0008})
```

0x0004 appears again, which means there must be a circle, to remember all pointer values we need an extra data structure for pointer storage and comparison.

The decoding process for the generated bytes[] 1st can be illustrated as follows:

```
decode(bytes[] lst)
= decode(1::ptrToBytes(0x0004))
           ::3::symbolToBytes(Node_t)
              ::2:: intToBytes (2)
                 ::0::intToBytes(10)
                 :: 1:: ptrToBytes(0x0008)
                     ::3::symbolToBytes(Node_t)
                        ::2:: intToBytes (2)
                           ::0::intToBytes (20)
                           ::1::ptrToBytes(0x0004))
= decode (3::symbolToBytes (Node_t)
           ::2:: intToBytes (2)
              ::0::intToBytes (10)
              :: 1:: ptrToBytes(0x0008)
                 ::3::symbolToBytes(Node_t)
                     ::2:: intToBytes (2)
                        ::0::intToBytes (20)
                        ::1::ptrToBytes(0x0004)) in ((t1)
                           *, 0x0004), null)
= decode (2::intToBytes (2)
           ::0::intToBytes (10)
           :: 1:: ptrToBytes(0x0008)
              ::3::symbolToBytes(Node_t)
                 ::2::intToBytes(2) /*two fields*/
                     ::0::intToBytes (20)
```

```
::1::ptrToBytes(0x0004)) in ((
Node_t*, 0x0004), null)
```

Once we have the name Node\_t, we can directly look up and retrieve its associative struct type in the mapping table, and then restore a new list on the receiver side like:

```
Node_t* head = (Node_t*) malloc(size of (Node_t));
```

During the left decoding process, we set up a table(see table 3) which records the values on both sender and receiver sides for each pointer, to help us conveniently restore the sender side point-to relationships in the receiver side.

pointer	value in sender	value in receiver
head	0x0004	0x0012
tail	0x0008	0x0016
head→next	0x0008	0x0016
tail→next	0x0004	0x0012
•••	•••	•••

Table 3: Pointer values in both sender and receiver

For example, assume in the receiver side pointer head equals to 0x0012, and its sender counterpart equals to 0x0004, then we have an entry like head-0x0004-0x0012 in our table. After we finished the restoration, we can also use this table to check whether the old pointer-to relationships are maintained correctly.

Let's continue decoding the bytes above, we have:

```
::2:: intToBytes (2)
                ::0::intToBytes (20)
                :: 1:: ptrToBytes(0x0004))
  head \rightarrow val = 10;
  head->next = (Node_t*) malloc(sizeof(Node_t)); //
      assume head->next = 0x0016
  ("Node_t" can be directly retrieved from the name-
      type mapping table)
  Pointer table:
  Pointer
                  sender
                              receiver
  head
                  0x0004
                               0x0012
  head->next
                  0x0008
                               0x0016
= decode (empty)
  head \rightarrow next \rightarrow val = 20;
  head \rightarrow next \rightarrow next = (Node_t) malloc(size of (Node_t))
      ;//assume 0x0020
  Pointer table:
  Pointer
                         sender
                                    receiver
  head
                         0x0004
                                     0x0012
  head->next
                        0x0008
                                     0x0016
                                     0x0020 (wrong value!)
  head->next->next 0x0004
   By checking the pointer table we know pointer "head→next→next"
should be an alias of pointer "head". So the new allocated value for
"head→next→next" should be updated immediately from 0x0020 to 0x0012
as follows:
= decode (empty)
  head \rightarrow next \rightarrow val = 20;
  head \rightarrow next \rightarrow next = 0x0012;
  head \rightarrow next \rightarrow next = head;
  Pointer table:
```

Pointer	sender	receiver
head	0x0004	$0 \times 0012$
head->next	0x0008	0x0016
head->next->next	0x0004	0x0012

# 3 Separation Framework

# 3.1 Program dependence graph

Program Dependence Graph(PDG) plays a key role in our separation framework. To build a PDG for a large program with multiple functions, we first build a PDG for each function, which means we first model all the intra-procedural dependences. Then, based on the caller-callee relationships, we build corresponding parameter trees[1] to model the inter-procedural dependences. We also use tree structures to represent the global data structures, and construct the data dependences between the global variables and their caller functions.

We develop a toolchain which can build instruction-grained PDGs for LLVM IRs. Our toolchain wraps up each IR instruction as a graph node, and adds two kinds of auxiliary nodes to help represent the inter-procedural dependences. So, we have three kinds of node in a PDG in total:

- (1) instruction node: used to represent an LLVM IR instruction;
- (2) **entry node**: used to represent the entry point of a function;
- (3) **parameter tree node**: used to build the parameter trees.

Accordingly, we have four kinds of edges:

- (1) **control dependence edge**: used to represent a control dependence;
- (2) **data dependence edge**: used to represent a data dependence;
- (3) parameter tree edge: used to connect the parameter tree nodes;

(4) **call edge**: used to connect the call site with the entry node of callee function. For indirect calls, we use a type-based approximation to connect the call site with all possible target callees with the same type.

## 3.1.1 Modeling intra-procedural dependences

The intra-procedural dependences consist of both control dependences and data dependences. The control dependences within a function can be captured easily with the classical post-dominator-tree-based algorithm[2]. Computing the data dependences is a little harder since we need to process two different kinds of data dependences separately, the **def-use dependences** and the **flow dependences**(**true data dependences**). The defuse dependence represents the data dependency between two statements with the definition-use association(DUA,see Fig 1.a), and the flow dependence represents the dependency between memory read and write operations(read-after-write,see Fig 1.b). In this paper, both the **anti-**dependence (write-after-read) and the **output-**dependence(write-after-write) are not in our consideration, and we only compute the flow dependence.

Figure 1: An example of two kinds of data dependences

The definition-use dependences can be detected easily by finding all

variables in a statement and then adding a dependence between it and the statement that defines the variable. For flow dependencies, since they only exist between the memory read and write statements, our algorithm for computing all of intra-procedural flow dependencies can be described as follows:

**Step 1**: Check each memory operation in the program, if it is a memory read, do Step 2; otherwise, continue to check the next memory operation.

**Step 2**: For each memory read  $r_i$ , check each memory write operation  $w_i$  in this function, if  $r_i$  and  $w_i$  access the same memory location,  $r_i \rightarrow w_i$  is a flow dependence. The alias analysis algorithm is required here, in our work, we use the DSA algorithm[3] to help compute the aliases because it is a kind of open-source, context-sensitive and field-sensitive algorithm that can be applied to large server applications[4].

## 3.1.2 Modeling inter-procedural dependences

The inter-procedural data dependency fully depends on the function parameter passing. So, the core part of modeling inter-procedural data dependency is how to represent the data dependency between the **actual parameters(arguments)** and the **formal parameters**. If the function parameter is a pointer, we need to further model the dependency associated with the value that the pointer points to. To represent the data layout of parameters in memory as precisely as possible, we model 4 parameter trees for each parameter:

**actual-in tree**: used to represent a new actual parameter before entering the callee function;

**actual-out tree**: used to represent the actual parameter when a call is finished;

**formal-in tree**: the callee analog of actual-in tree, used to represent the formal parameter before the callee execution;

formal-out tree: the callee analog of actual-out tree, used to represent

the formal parameter after the callee execution.

For each function  $^1f$ , we only need to build its formal-in and formal-out trees once because f only has one function body. On the other hand, the number of actual-in and actual-out trees depends on how many calls we have in a program. If f is directly called by another function q, we build the actual-in and actual-out trees at the call site which is within q. So, each direct call for f matches exactly one pair of actual-in and actual-out trees. However, if f is called indirectly, it is impossible for us to exactly locate the position of callee function. Our solution is to approximately retrieve all possible candidate functions with the same type as f and build actual-in/out trees for each of them, which means some redundant actual trees will be built inevitably.

The process of building a parameter tree is shown in Algorithm 1. Each incoming parameter p corresponds to a root. If p is a pointer, we insert the value that p points to into the tree as the child of p and process this value to build subtrees recursively; otherwise if p is a struct, we retrieve each field  $f_i$  in p and insert  $f_i$  as a child of p, and then use  $f_i$  as input to build a subtree; if p is neither a pointer nor a struct, which means it must be a variable of atomic type<sup>2</sup>(e.g. int, float, char...), p will be inserted as a leaf. Actually the parameter tree for an atomic variable always shrinks to a single node.

One problem about representing parameters with tree structures is some parameters may have recursive data structures(e.g. linked list) that can lead to parameter trees of infinite depth. To solve this problem Graf[1] proposes an algorithm to unfold the recursive data structures. In our framework, we directly borrow that algorithm to help build parameter trees. A example of building parameter trees with recursive data structures is listed in Figure 2.

We also use the tree data structure to model the global variables for better field-sensitivity. The algorithm for building the global variable trees is completely the same as building the function parameter trees.

<sup>&</sup>lt;sup>1</sup>Library functions(e.g.scanf, printf, exit...) will not be unfolded as subgraphs but represented as common nodes.

<sup>&</sup>lt;sup>2</sup>For simplicity, we take string as an atomic type also.

```
Algorithm 1: building a parameter tree
   BuildTree(p,T)
   Input : p- parameter; T- a pointer which points to the tree root
   Output: a constructed tree represented by T
   T \rightarrow root = p;
   if p is a pointer then
       T \rightarrow root \rightarrow firstchild = dere ference(p); /* insert *p */
       BuildTree(dereference(p), T \rightarrow root \rightarrow firstchild);
   else
       if p is a struct then
           for each field f_i in p do
               T \rightarrow root \rightarrow appendchild(f_i);
               BuildTree(f_i, T \rightarrow root \rightarrow getchild(i));
           end
       else
                                                      /* atomic parameter */
       end
   end
                                              Node*
struct Node*{
                                                            Node
                                               head
  int value;
  Node *next;
                                                                  Node*
                                                    int value
                                                                               Node
struct Node *head = NULL;
                                                                   next
head = malloc(sizeof(struct Node));
buildlist (head);
                                                                                       Node*
                                                                        int value
                                                                                       next
        (a) a linked list program
                                                 (b) an unfolded parameter tree
```

Figure 2: An example of parameter trees with recursive data structure

## 3.1.3 Example: encrypt a password

Let us see a real example. The toy program in Figure 2 includes a function with simple greeting, a function for password encryption and the main function. In line 2, we mark array password as a piece of sensitive data. Figure 3 is the PDG model for this toy program. We omit most of the simple intra-dependences, and only keep the most interesting part about how to use parameter trees to represent the inter-procedural data dependency.

```
1 static char username [20];
   static char __attribute__(sensitive) password[20];
4 int greeter(char *str){
5
     if(str == NULL)
6
      return 1;
7
     printf("Welcome %s!"\n, str);
8
     return 0;
9
   }
10
11 int encrypt(char *str,int key){
12
     unsigned int i;
13
     for(i = 0; i < strlen(str); ++i)
14
       str[i] = str[i] - key;
15
16
     return 0;
17 }
18
19 int main(){
20
     printf("Create your username: \n");
21
     scanf("%s", username);
22
     if (greeter (username) == 1)
23
       printf("Invalid user!\n");
24
     printf("Enter your password: \n");
25
     scanf("%s", password);
26
     printf("password:%s\n", encrypt(password,5));
27
     return 0;
28 }
```

Figure 2. A toy C program to encrypt a password

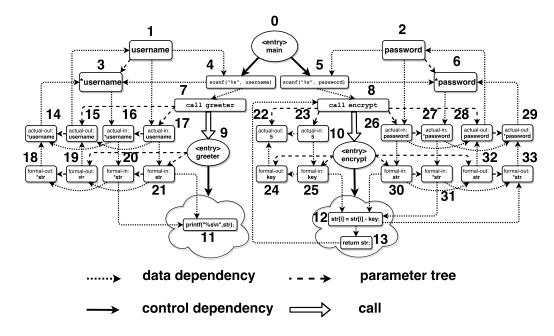

Figure 3: The program dependence graph of our toy program.

In Figure 3, we construct two trees for global arrays username and password separately. Considering all arrays passed to functions are converted into pointers in C, we directly represent them with the form of char\* instead of char[], and by doing this we can show the data dependency better. As you can see on the upper-left part, node 1, which is the root of the global variable tree for username, represents the pointer that points to the username string; while node 3 represents the content that pointer points to, i.e., the string itself. By algorithm 1 clearly node 3 is the child of node 1, and also a leaf since we take string as an atomic type just as we mentioned before. In the main function, we need to set up a def-use data dependence edge  $(1 \rightarrow 4)$ , and a flow dependence data dependence edge  $(4 \rightarrow 3)$  since the operation scanf uses the pointer "username" first and then modifies the value that pointer "username" points to.

Next, we have a data dependence edge  $(4 \rightarrow 7)$  because we take the call operation(node 7) as a kind of use of "username". We use a call edge $(7 \rightarrow 9)$  to connect the call site(node 7) in the caller function(main) and the entry node of the callee function(greeter). The function body of greeter is abstracted as a cloud-like region, connected with its entry node through

an abstract control dependence edge (9  $\rightarrow$  11).

Now we can use parameter trees to represent the parameter passing between main and greeter. We let the call node(node 7) dominate the actual-in(node 16, node 17) and actual-out(node 15, node 14) trees,and the entry node of greeter(node 9) dominate the formal-in(node 21 and 20) and formal-out(node 19 and 18) trees. There are two kinds of data flow when the parameter is a pointer: one is the data flow of the pointer itself, and the other is the data flow of the value that pointer points to(pointee). On this graph, the data flow of the pointer itself(username) can be represented by a node sequence  $1 \rightarrow 17 \rightarrow 21 \rightarrow 19 \rightarrow 15 \rightarrow 1$ , which is a loop actually. Accordingly, the data flow of the pointee of "username" can be represented with the sequence  $3 \rightarrow 16 \rightarrow 20 \rightarrow 18 \rightarrow 14 \rightarrow 3$ . However, there is only memory read(node 11) but no write operation in function greeter, so we only have two data dependence edges  $(21 \rightarrow 11)$  and  $(20 \rightarrow 11)$ , which both come from the caller to callee.

The PDG construction for (encrypt) is similar. The first parameter is just an integer so each parameter tree is simply constructed as a single node. There is a data dependence edge  $(25 \rightarrow 12)$  since the formal parameter "key" is read by "str[i] = str[i] - key;". One important data dependence edge in encrypt is  $(12 \rightarrow 33)$ , which represents that we update the buffer that the pointer "str" points to inside the callee function. Finally, we have a a data dependence edge  $(13 \rightarrow 8)$  to represent the data flow of return value.

# 3.2 PDG-based separation algorithm

After we have a PDG for a program, we can separate this program into two slices by partitioning its PDG into two cuts. Simply speaking, we first annotate some sensitive data in the program with the \_\_attribute\_\_ grammar(see line 2 in Figure 2) and take the corresponding graph nodes as the source, and start from the source nodes to do a greedy coloring along the data dependence edges on the graph. After the coloring finished, we get two sets of graph nodes, one consists of all colored nodes and the other consists of all uncolored nodes. In the set of colored nodes, we check each node one by one, if it corresponds to a global variable, we directly mark

that global variable as sensitive, and if it corresponds to a statement within a function, we mark that function as sensitive. Ultimately, all the sensitive functions and sensitive global variables will be separated from the original program as an independent slice, and we call it "sensitive slice". On the other hand, the left global variables and functions that are non-sensitive form another slice, named as "non-sensitive slice" for simplicity.

A detailed description of our separation is in Algorithm 2. and this dependency may be transitive since we omit some intra de-

pendences for the main function. greeter(username),

When username is used in a function, as the situation on node 4, we set up a data dependence edge from node 1 to node 4 to represent the def.

we draw a parameter tree edge from node 1 to node 3

In the global variable tree for username, , and since it is a pointer

Node 1 the the root of global variable treerepresents the address of

Let us use the toy program in Fig.1 to show our basic working flow for the PDG construction.

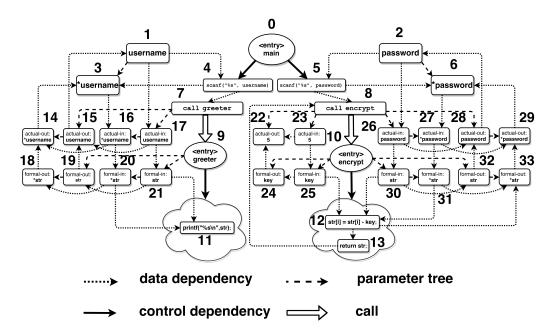

Figure 4: The program dependence graph of our toy program.

We use solid lines to represent the control dependences, and dotted

### **Algorithm 2:** PDG-based program separation

```
separate(p,T)
Input : PDG(N, E) — a directed graph, where N is the set of nodes
         and E is the set of edges;
         function – set — a set which contains all the functions in the
input module;
         source – set — a set which contains all the nodes that marked
as "sensitive" on the PDG;
         Queue — a priority queue used for the greedy graph
coloring;
         colored – set — a set which contains all colored graph nodes
during the coloring
Output: a constructed tree represented by T
T \rightarrow root = p;
if p is a pointer then
   T \rightarrow root \rightarrow firstchild = dere ference(p); /* insert *p */
   BuildTree(dereference(p), T \rightarrow root \rightarrow firstchild);
else
   if p is a struct then
       for each field f_i in p do
           T \rightarrow root \rightarrow appendchild(f_i);
           BuildTree(f_i, T \rightarrow root \rightarrow getchild(i));
       end
   else
                                                /* atomic parameter */
   end
end
```

lines to represent the data dependences.

The real difficulty is how to represent the inter-procedure data dependency. Out solution is using parameter trees, which

One problem when using parameter trees is elegantly deal with parameters with recursive data structures(e.g. linked list), which can lead

to parameter trees of infinite depth. On this issue, we borrow the idea of J. Graf's work[1]. ...

illustrate how cyclic(recursive) structures are accommodated by ... linked list, tree...
